

Applied Cryptography

CPEG 472/672

Lecture 4A

Instructor: Nektarios Tsoutsos

Cryptographic Security

- ◉ We want to quantify security
 - ◉ Not necessarily binary (secure, insecure)
 - ◉ What is the effort to break a cipher?
- ◉ Two types of security
 - ◉ Informational Security
 - ◉ E.g. One Time Pad (impossible to break)
 - ◉ Theoretical focus
 - ◉ Computational Security
 - ◉ E.g. AES (can't break in reasonable time)
 - ◉ Practical focus

Computational Security

- ◉ Expressed using
 - ◉ t : number of operations
 - ◉ e : probability of attack success
- ◉ We say (t, e) -secure cipher
 - ◉ Attacker that performs at most t operations has success probability at most e
- ◉ Ideal block cipher with n -bit key:
 - ◉ Here, the best attack is brute force
 - ◉ $(t, t/2^n)$ -secure cipher

Measure security level in bits

- ◉ Assume successful attack (e almost 1)
 - ◉ We can express security as the number of operations t required for the attack
 - ◉ t -bits of security $== 2^t$ steps required
- ◉ Security level may differ from key size
 - ◉ E.g., RSA with 2048-bit secret key offers ~ 100 bits of security

Attack parameters

- ◉ Parallelism?
 - ◉ Sequentially dependent operations
 - ◉ Independent operations
- ◉ Memory cost?
 - ◉ How much memory is consumed?
 - ◉ How many memory lookups are needed?
- ◉ Precomputation (offline stage)
 - ◉ Time/memory tradeoff
- ◉ Number of targets

Achieving security

- ◉ How to ensure ciphers can't be broken?
- ◉ **Provable security**
 - ◉ Mathematical proofs that algorithms can't be broken
 - ◉ Security reductions: Any method to break the cipher also yields a method to solve a known hard problem
- ◉ **Heuristic security**
 - ◉ Evidence that highly skilled people tried and failed

Provable Security

- ⊙ Proofs relative to a hard math problem
 - ⊙ E.g., factorization of large integers
 - ⊙ Breaking the cipher is as hard as solving a mathematical problem
- ⊙ Proofs relative to another crypto problem
 - ⊙ We can only break the given cipher if we can first break another crypto primitive
 - ⊙ E.g., A Feistel network is secure as long as the underlying function F is a secure PRP

Heuristic Security

- ◉ Provable security does not apply to all cryptographic algorithms
 - ◉ Many symmetric ciphers don't have a proof
- ◉ Heuristic Security
 - ◉ AES can't be reduced to another problem
 - ◉ **AES itself is the hard problem!**
 - ◉ Experts try to break reduced versions of algorithms (e.g., cipher with fewer rounds)
 - ◉ Establish a security margin

Key generation

- ◉ Random keys (e.g., via PRNG)
 - ◉ Symmetric (e.g., AES)
 - ◉ Asymmetric (primes for RSA)
 - ◉ Requires a key generation algorithm
 - ◉ `openssl genrsa 4096`
- ◉ Using a password
 - ◉ Requires a key derivation function
- ◉ Using a key agreement protocol
 - ◉ Two or more parties establish a shared a key

Protect generated keys

- ◉ Wrap keys using AES encryption
 - ◉ `openssl genrsa -aes128 4096`
 - ◉ User provides a password to unlock
- ◉ Generate keys from password on the fly
 - ◉ Vulnerable if password is weak
 - ◉ Dictionary attacks
- ◉ Store key using secure hardware
 - ◉ USB dongle
 - ◉ User enters a password to unlock
